Abstract
Object correlations are common semantic patterns in virtual reality systems. They can be exploited for improving the effectiveness of storage caching, prefetching, data layout, and minimization of query-response times. Unfortunately, this information about object correlations is unavailable at the storage system level. Previous approaches for reducing I/O access time are seldom investigated. On the other side, data mining techniques extract implicit, previously unknown and potentially useful information from the databases. This paper proposes a class of novel and efficient pattern-growth method for mining various frequent sequential traversal patterns in the virtual reality. Our pattern-growth method adopts a divide-and-conquer approach to decompose both the mining tasks and the databases. Moreover, our efficient data structures are proposed to avoid expensive, repeated database scans. The frequent sequential traversal patterns are used to predict the user navigation behavior and help to reduce disk access time with proper placement patterns into disk blocks. We also define the terminologies such as paths, views and objects used in the model. We have done extensive experiments to demonstrate how these proposed techniques not only significantly cut down disk access time, but also enhance the accuracy of data prefetching.

Keywords: Virtual reality, frequent pattern mining, clustering, object correlations, data layout

1. Introduction
With the advent of advanced computer hardware and software technologies, virtual reality (VR) are becoming larger and more complicated. To satisfy the growing demanding for fidelity, there is a need for interactive and intelligent schemes that assist and enable effective and efficient storage management. Unfortunately, it is not an easy task to exploit the intelligence in storage systems. One primary reason is the system latency between VR applications and storage systems. In such a case, VR do not consider the problem of access times of objects in the storage systems. They always simply concerned about how to display the object in the next frame. As a result, the VR can only manage data at the rendering and other related levels without knowing any semantic information such as semantic correlations between data [6]. This motivates a more powerful analysis tool to discover more complex patterns, especially semantic patterns, in storage systems. Therefore, the aim of our work is to decrease this latency through intelligent organization of the access data and enabling the clients to perform predictive prefetching.

In this paper, we consider the problem and solve this using data mining techniques [1,2]. Clearly, when users traverse in a VR, some potential semantic characteristics will emerge on their traversal paths. If we collect the users’ traversal paths, mine and extract some kind of information of them, such meaningful semantic information can help to improve the performance of the interactive VR. The rest of this paper is organized as follows. Related works are given in Section 2. The Problem definitions and suggested mining algorithm are explained with illustrative examples shown in Section 3. Section 4 presents our experiment results. Finally, we summarize our current results with suggestions for future research in Section 5.

2. Related Works
In this subsection, we will briefly describe related works about VR, sequential pattern mining and pattern clustering, respectively.

2.1. Virtual Reality Methods
Since the navigation in VR consists of many different detailed objects, e.g., of CAD data that cannot all be stored in main memory but only on hard disk. Many techniques were proposed for rendering
consumptions. should be developed with the constraints of memory appropriate data structure and an efficient technique capacities [10]. To meet these requirements, an additional data could exceed the available capacities [10]. To meet these requirements, an appropriate data structure and an efficient technique should be developed with the constraints of memory consumptions.

2.2. Sequential Pattern Mining Methods

Sequential pattern mining was first introduced in [3], which is described as follows. A sequence database is formed by a set of data sequences. Each data sequence includes a series of transactions, ordered by transaction times. This research aims to find all the subsequences whose ratios of appearance exceed the minimum support threshold. In other words, sequential patterns are the most frequently occurring subsequences in sequences of sets of items. A number of algorithms and techniques have been proposed to deal with the problem of sequential pattern mining. Many studies have contributed to the efficient mining of sequential patterns [3,7]. Almost all of the previously proposed methods for mining sequential patterns are apriori-like[3]. Sequential pattern mining algorithms, in general, can be categorized into three classes: (1) Apriori-based: horizontal partition methods and GSP[2] is one known representative; (2) Apriori-based: vertical partition methods and SPADE[4] is one example; (3) projection-based pattern growth method, such as the famous FreeSpan [7] and PrefixSpan algorithms [3].

3. Traversal Histories Mining and Problem Formulation

In this section, we extract the useful information in the access history in the form of sequential patterns. In order to mine for sequential patterns, we assume that the continuous client requests are organized into discrete sessions. Sessions specify user interest periods and a session consists of a sequence of client requests for data items ordered with respect to the time of reference [8]. The client request consists of the objects which a client browse and traverse at will in the WT. We denote this type of clients request as view. A session consists of one or more views. In correspond to with terminologies used in data mining, a session can be considered as a sequence. The whole database is considered as a set of sequences. Formally, let \( \Sigma = \{l_1, l_2, ..., l_m\} \) be a set of \( m \) literals, called objects (also called items)[2]. The view \( v \) is defined as snapshot of sets of objects which a user observes during the period. A view (also called itemset) is an unordered, non-empty set of objects. A sequence is an ordered list of views. We denote a sequence \( s \) (also called transaction) by \( \{v_1, v_2, ..., v_n\} \), where \( v_j \) is a view and ordered property is obeyed. We also call \( v_j \) an element of the sequence. An item can occur only once in an element of a sequence, but can occur multiple times in different elements. We assume, without loss of generality, that items in an element of a sequence are in lexicographical order.

A sequence \(<a_1, a_2, ..., a_n>\) is contained in another sequence \(<b_1, b_2, ..., b_m>\) if there exist integers \( i_1 < i_2 < ... < i_n \) such that \( a_i \subseteq b_i \) for \( 1 \leq i \leq n \). For example, \(<(a)(b, c)(a, d, e)>\) is contained in \(<(a, b)(b, c)(a, b, d, e, f)>\), since \( (a, b) \subseteq (a, b, c) \subseteq (b, c) \), and \((a, d, e) \subseteq (a, b, d, e, f)\). However, the sequence \(<(c)(d)>\) is not contained in \(<(c, d)>\) and vice versa. The former represents objects \( c \) and \( d \) being observed one after the other, while the latter represents objects \( c \) and \( d \) being observed together. In a set of sequences, a sequence \( s \) is maximal if \( s \) in not contained in any other sequence. Let the database \( D \) be a set of sequences and ordered by increasing recording time. Each sequence records each user’s traversal path in the VR system. The support for a sequence is defined as the fraction of \( D \) that “contains” this sequence. A sequential pattern \( p \) is a sequence whose support is equal to or more than the user-defined threshold. Sequential pattern mining is the process of extracting certain sequential patterns whose support exceeds a predefined minimal support threshold. Given a database \( D \) of client transactions, the problem of mining sequential patterns is to find the maximal sequences among all sequences that have a certain user-specified minimum support. Each maximal sequence represents a sequential pattern.

Finally, we will define our problem as follows. Given a sequence database \( D = \{s_1, s_2, ..., s_n\} \), we design an efficient mining algorithms to obtain our sequential patterns \( P \) for reducing the disk access time.

3.1. Pattern Growth-based Mining Algorithms

In this section, we will explain our sequential pattern mining method, called View-based Sequence Pattern Mining (VSPM). The main ideas come from
both bounded-projection and pattern appending mechanisms. The bounded-projection mechanism has one special characteristic, i.e., it always projects the remaining sequence recursively after a new sequential pattern found. They will not mine the objects across the different prefix views. As a result, we would mine the trimmed database recursively. The pattern appending mechanism uses the concept of prefix property. When we want to find a new sequential pattern in our database, we use the sequential pattern found in previous round as prefix, and append a new object as the new candidate pattern for verification. If the candidate pattern satisfied the minimum support, we regard it as a new sequential pattern and create a bounded projection of it recursively. In order to explore the interesting relationships among these objects, we propose two different kinds of appending methods – called Intra-View-Appending method and Inter-View-Appending method. The Intra-View-Appending method is used to append a new object in the same view, and the Inter-View-Appending method is used to append a new object in the next view. Demonstration example will be given later. The following is the pseudo codes of view sequence mining algorithm.

**View-based Sequential Pattern Mining (VSPM) Algorithm**

// D is the database. P is the set of frequent patterns, and is set to empty initially.

**Input:** D and P.

**Output:** P.

1. Find length-1 frequent sequential patterns.
2. **While** (any projected sub-database exits) do
3. **Begin**
4. Project corresponding sub-sequences into sub-databases under the intra-view appending and inter-view appending.
5. Mine each sub-database corresponding to each projected sub-sequence.
6. Find all frequent sequential patterns by applying step 4 and step 5 on the sub-databases recursively.
7. **End;** // while
8. return P;
9. **End;** // procedure VSPM ends

**Example 1 (VSPM).** Given the traversal data base S and min_support = 3. The final mining result is depicted in Fig. 1. Path1: <(1, 2)(3, 4)(5, 6)>.
Path2: <(1, 2)(3, 4)(5)>
Path3: <(1, 2)(3)(4, 5)>

Besides, in Figure 1, the patterns which contain item 6 are circled. They show that the differences between projected-based mining and non-projected-based mining. In other words, without projecting mechanism, we have to expand eight sub-databases for candidates (i.e., two “stop” without circled plus six “stop” with circled). Compared to this case, with projecting mechanism, we only expand two sub-databases for candidates (i.e., “stop” without circled).

4. **Performance Evaluation**

We use the virtual power plant model from http://www.cs.unc.edu/~walk/ created by Walkthrough Laboratory of Department of Computer Science of University of North Carolina at Chapel Hill.

Our main performance metric is the average latency. We also measured the client cache hit ratio. A decrease in the average latency is an indication of how useful the proposed methods are. The average latency can decrease as a result of both increases cache hit ratio via prefetching methods and better data organization in the disk. An increase in the cache hit ratio will also decrease the number of requests sent to server and, thus, lead to both saving of the scare memory source of the server and reduction in the server load. The performance of our traversal database is reported as follows. First, we follow the procedure described in [2] to set up out data set parameters. The meanings of all parameters are listed in Table 1. From Fig. 2and 3, we can see that VSPM is as efficient as PrefixSpan does, but it is much more efficient than SPADE, FreeSpan, and GSP.

Table 1. Parameters for our traversal data set

![Fig. 2 Execution time with respect to various support thresholds using our real data set-1.](image-url)
**Definition 1: View-radius**

The view radius is defined as the radius of the visible circle in the VR. As the radius increases, the more objects are observed. In other words, it controls how many objects are observed at the same time in one view.

In the meanwhile, we select the different view-radius for comparison. Fig. 4 and 5 show the results. Algorithm with VSPM outperforms other algorithms without VSPM. Since the clustering mechanism can accurately support prefetching objects for future usage. Not only the access time is cut down but also the I/O efficiency is improved.
