**ABSTRACT:** In this work the design of a nano structured ceramic membrane is carried out for fuel cell applications. However the innovation is that a membrane porous network is modified through its immersion in silica based solution and in a palladium solution to form composite membrane. Subsequently, the development of hybrid ceramic gas separation membrane elaborates on the recovery of hydrogen from fuel reforming unit for use in fuel cell applications. To enhance the efficiency of the fuel cell, clean hydrogen using membranes with a high permeability and selectivity for H<sub>2</sub> over N<sub>2</sub> and CO<sub>2</sub> are a necessity.

**KEYWORDS:** ceramic membrane; palladium membrane; energy security; carbon capture; hydrogen production; gas separation; fuel cell.

## 1 INTRODUCTION

Nanostructured hybrid materials have the promise to facilitate renewable energy to cover up for the anticipated energy gap and related ecological problems. Hydrogen utilization has therefore paved way to the fabrication of very operational energy generating devices including fuel cell. High-efficiency fuel cell operation from clean hydrogen can be utilized in all energy sectors, however its application in vehicular transportation and distributed power are more important. Accordingly fuel cell with clean hydrogen-rich fuel is top among solutions sort for the transitional process to a CO<sub>2</sub>-zero emission economy and a pathway to sustainable energy in the nearest future. Production of a cost efficient and sustainable clean hydrogen is among challenges which must be surmounted for the evolution from carbon based (fossil fuel) energy economy to hydrogen based economy[1]. Therefore an efficient and cost efficient technology for gas separation is highly required that will have the effect of reducing the overall expenditure of the entire system. Membrane technology at the moment is being highly applied widely in hydrogen separation. Membrane applications have remained a more energy efficient substitute to more conventional methods in gas separations. The outstanding difference in the flow rate and permeation features during the separation processes involving multi-component gas mixtures makes the membrane a

good candidate for gas separation[2]. Accordingly, inorganic membranes show brilliant evidence of chemical and physical properties, high temperature stability as well as unresponsiveness to sarcastic environment, homogenous pore structure and substantial tensile strength which will conquer the limitations of polymer membrane. Subsequently Electroless plating method for the deposition of palladium films over porous support is gaining increasing attention and preferred over other methods due to its ease of coating over any surface of any shape[3]. Electroless plated palladium membranes also have excellent resistance to corrosion, involve simple equipment and low cost and also avoids accumulation of the deposits around the substrate edges to ensure uniformity of coating. However, it also has its drawbacks such as its time consuming nature as a result of the several treatment steps involved and also the threat of impurities which are usually encountered during the sensitization and activation step prior to electroless plating. The sensitization and activation steps make the electroless plating process prone and susceptible to contamination from Tin, Sn[4] impurities which may lead to less active palladium layer and by implication result in low hydrogen flux. In the conventional electroless plating process, the major problem is how to achieve uniform densification of the palladium layer and also prevent mass transfer from the film into the solution. Prior to the deposition of the metal on the support, the

sensitization and activation steps are carried out on the porous ceramic substrate so as to create catalytic sites on the non-metallic surfaces and to also stimulate the adsorption of the metal ions, enhance strong adhesion of the Pd nuclei on the substrate and eliminate induction period of the metal to ensure better uniformity of coating and improved membrane quality. In this work, we developed a new method of support modification during electroless plating which skips the sensitization step and avoided the threat of Tin impurities while drastically reducing the induction time and overall duration of the electroless plating process[5].

## 2 EXPERIMENTAL

In this work two membrane supports were designed. A conventional 15nm pore size alumina ceramic membrane with an effective permeable length of 358mm, outer and inner diameter of 10mm and 7mm respectively and membrane surface area of  $0.0062\text{m}^2$  used for gas permeation experiment.

For the second membrane, thin Pd films were deposited on different ceramic  $\alpha$ -alumina supports of 30nm average pore size. The porous alumina support has the specification inner diameter, 7mm, outer diameter 10mm, effective length= 0.34m. The support was first dried at  $65^\circ\text{C}$  in an oven for 2 hours to remove any moisture and stored for 4 hours at room temperature. The support was then calcined at 873K for 24 hours and stored overnight at room temperature after which it was modified through a 2step sensitization and activation procedure in order to seed it with Pd nuclei to create catalytic sites and ensure in a uniform deposition of the metallic layer. A second  $\alpha$ -alumina support was prepared based on the same procedure as the first support. A 5mM Sn solution and 5mM d[4] solution was used as sensitization and activation solutions respectively. Both supports were sealed at both ends to prevent internal deposition before being immersed in the sensitization solution for 5 minutes followed by rinsing in distilled water. In the conventional electroless plating, the first support was immersed in the sensitization solution for 5 minutes and rinsed with distilled water. The support was then rinsed with the activation solution for another 5 minutes and again rinsed in distilled water. This procedure is repeated 10 times to obtain a more uniformly seeded support. After the sensitization and activation procedure, the seeded support was dried overnight at room temperature. For the new method, the second support was modified with Boehmite sol through the sol gel process or dip coating method prior to the activation step after which it was inserted in the Pd solution for 5 minutes and rinsed with distilled water. The procedure was repeated 10 times. The

sensitization step was not involved in this case. For the sol gel process, a Boehmite solution of 46.1g AlOOH dissolved in 760mL distilled water was prepared. The support was dipped into the solution for 30 minutes under continuous stirring after which it was removed and dried at  $65^\circ\text{C}$  for 2 hours. This procedure was repeated 3 times which implies that 3 sequential dips were carried out.

## 3 RESULTS AND DISCUSSION

Figure 3 depicts a plot of the flow rate of  $\text{H}_2$ ,  $\text{CO}_2$ ,  $\text{O}_2$  and  $\text{N}_2$  gases versus pressure drop for the commercialized 15nm ceramic membrane while figure 4 is an SEM image of its inner surface. From the graph it can be observed that hydrogen gas permeated faster with increase in feed pressure through the modified ceramic inorganic membrane more than the other three single gases,  $\text{O}_2$ ,  $\text{N}_2$  and  $\text{CO}_2$ . Accordingly hydrogen gas with molecular weight of 2 had the highest flow rate of 5.045l/min above 4bars. Similarly, Figure 5 shows the morphology of the composite palladium membrane with a thickness of  $2\mu\text{m}$ . Figure 6 and 7 respectively show the transport of Hydrogen through the palladium composite membrane at temperature ranging from 623k – 723k. Sievert's law was observed to hold for these temperatures.

#### 4 CONCLUSION

Single gas permeation tests carried out using the ceramic and palladium composite membrane have shown that the membranes exhibits good performance and higher permeability of hydrogen gas with high flow rate. For composite palladium membrane, a thickness of about 2  $\mu m$  was achieved for both Palladium membranes prepared with and without sensitization. The  $H_2$  flux increased with temperature for the palladium membrane prepared with sensitization. It can be observed that skipping the sensitization step increased the hydrogen flux. This indicates that there was some hindrance to hydrogen permeation during sensitization which was avoided by skipping the sensitization step during

preparation of the second palladium membrane. Skipping the sensitization step also reduced the induction period during the plating of the second palladium membrane. Moreover, the time duration for the electroless plating was reduced by about 1 hour which ensured a more effective plating process devoid of contamination. Overall, the results have shown that both the ceramic membrane and the palladium membrane have a high level of hydrogen gas selectivity characteristics which is a good indication that they can be installed in a fuel processing unit for  $H_2$  recovery from the rich  $CO_2$  stream. Work is currently being undertaken to optimize the performance of these novel systems for various applications.
