Abstract: Hexagonal Mn₂O₃ nanoplates were synthesized by a hydrothermal method and then a annealing process. The Hexagonal Mn₂O₃ nanoplates prepared at hydrothermal temperature 200 °C exhibited the best electrochemical properties with a high reversible capability and cycling stability. It still retains a high capacity of 565 mAh g⁻¹, even after 100 cycles, as anode materials for lithium-ion batteries. The good electrochemical performance for the porous Mn₂O₃ microspheres can be attributed to its high surface area and mesoporous structure.

Introduction

Recently, a variety of metal oxides has been investigated as potential electrode materials for LIBs. Among the numerous candidates as LIB anodes, three representative types of metal oxides stand out with distinct lithium storage mechanisms and characteristics, namely tin dioxide⁴¹, titanium dioxide⁴², and many transition metal oxides.

Manganese oxides, which include MnO, MnO₂, Mn₂O₃, and Mn₃O₄, have received great interest recently with the advantages of earth-abundance, nontoxicity, and cost effectiveness⁴³⁻⁴⁴. Among them, Mn₂O₃ electrode materials for LIBs have a high theoretical capacity of 1018 mAhg⁻¹ and lower operating voltage (average discharge voltage at 0.5 V and charge voltage at 1.2 V). Much attention has been paid to improve the cycling performance of Mn₂O₃⁴⁵⁻⁴⁷.

In this work, we report that the hexagonal Mn₂O₃ nanoplates were synthesized by a hydrothermal method and then a annealing process. The electrochemical performances of the as-prepared hexagonal Mn₂O₃ nanoplates as anode materials of LIBs were also investigated.

Experimental

Synthesis and characterization of the samples

All chemicals were of analytical grade and were used without further purification. In a typical experiment, 0.5mmol MnAc₂·4H₂O was first dissolved in 30 mL deionized water at room temperature under magnetic stirring. Then 2 mL of N₂H₄·4H₂O (85%) was added into the above solution. The mixture was poured into and sealed in a Teflon-lined stainless steel autoclave of 50 mL capacity. The autoclave was heated to and maintained at 160-200 °C for 12 h and then air-cooled to room temperature. The product was collected by filtration, washed with distilled water and ethanol, and then dried under vacuum at 60 °C for 10 min. The obtained powders were heated in air at 600 °C for 4 h (at a heating rate of about 4 °C/min) to synthesize Mn₂O₃ nanoplates (denoted as Mn₂O₃-160, Mn₂O₃-180, and Mn₂O₃-200, respectively).

The crystallinity and structure of the samples were characterized by X-ray diffraction (XRD),
using a Rigaku X-ray diffractometer with Cu Kα radiation (λ = 1.5406 Å). Scan electron microscopy (SEM) images were carried out with a VEGA3 TESCAN electron microscopy.

The electrochemical characterization was performed using CR2032 coin-type test cells. The cell consisted of a cathode with the composition of 70 wt.% active materials, 20 wt.% carbon black, and 10 wt.% PVDF, a lithium metal anode separated by a Celgard 2400 microporous film. The electrolyte was 1 mol L⁻¹ LiPF₆ (EC) and (DEC) (1:1). The charge–discharge tests were galvanostatically performed over 0.01 to 3.0 V at different current densities.

Results and discussion

The XRD pattern of the final products is depicted in Figure 1d. All the diffraction peaks in the XRD pattern can be indexed to body-centered cubic Mn₂O₃, according to the standard XRD data file (JCPDS file no. 78-0390). No peaks of impurities can be detected from the XRD pattern.

![Fig. 1. XRD patterns of the Mn₂O₃ samples.](image)

The surface morphological features of the samples were investigated by SEM in Fig.2. The products display a nanoplates structure without aggregation while still maintaining the original plate-like morphology. It is well known that the particle size, particle size distribution and morphologies of the samples will directly influence the electrochemical performance of the electrode materials. Considering their nanoplates structures favoring the diffusion of Li⁺ ions and electrode–electrolyte contacts during the electrochemical reaction, the Mn₂O₃ nanoplates are expected to improve the electrochemical performance.

The electrochemical performances of Mn₂O₃ were measured via coin cell testing. Fig. 3 illustrates the discharge–charge profiles of the Mn₂O₃ nanoplates as anode materials for rechargeable lithium batteries at a current density of 100 mA g⁻¹ at room temperature in a potential window between 0.01 and 3.0 V (versus Li⁺/Li). From these, a large irreversible capacity at the first cycle is observed. The specific capacity of the Mn₂O₃-160 and Mn₂O₃-180 showed an obvious decrease with cycling, from 1047 and 1140 mAh g⁻¹ for the first cycle to 597 and 598 mAh g⁻¹ for the 100th cycle, whereas Mn₂O₃-200 exhibits the best performance for Li⁺ insertion, the Mn₂O₃-200 delivers a larger initial capacity of 1281 mAh/g and shows a high reversible capacity of 1147 mAh
g\(^{-1}\) for the second cycle, which is much higher than what was reported for those samples, which is higher than the theoretical value (1018 mAh g\(^{-1}\)). The excess capacities could be associated with the decomposition of the electrolyte at low voltages generating a solid electrolyte interphase (SEI) layer and the further lithium storage by interfacial charging at the metal/Li\(_2\)O interface. It still retains a high capacity of 620 mAh g\(^{-1}\) after 100 cycles. It is obvious that the Mn\(_2\)O\(_3\)-200 electrode shows much improved cycling performance with higher specific capacities at the same cycle with the same current density, as compared with the other samples, which may be attributed its bigger porous structure.

**Fig. 3.** (a) the first, (b) 100\(^{th}\) discharge/charge curves and (c) cycling performance of the Mn\(_2\)O\(_3\)-160, Mn\(_2\)O\(_3\)-180, and Mn\(_2\)O\(_3\)-200; (d) cycling performance of the Mn\(_2\)O\(_3\)-200 electrode at various current densities.

To better understand the electrochemical behavior of the Mn\(_2\)O\(_3\)-200 nanoplates, we also investigated its rate performance as shown in Fig.3d. The cell shows good rate capability with average discharge capacity of 676, 489, and 389 mAh g\(^{-1}\) when the current density increased stepwise to 100, 200, and 500 mA g\(^{-1}\), respectively. Upon altering the current density back to 100 mA g\(^{-1}\), an average discharge capacity as high as 556 mAh/g could be recovered. These results demonstrate that the nanoplates structure Mn\(_2\)O\(_3\) has great potential as high-rate anode material in lithium-ion batteries.

**Conclusions**

In summary, Mn\(_2\)O\(_3\) nanoplates have been synthesized by a facile method. The Mn\(_2\)O\(_3\)-200 nanoplates exhibited a high reversible capacity of 1147 mAh g\(^{-1}\), it still retains a high capacity of 620 mAh g\(^{-1}\), even after 100 cycles at a current density of 100 mA g\(^{-1}\). These results clearly demonstrate that the Mn\(_2\)O\(_3\)-200 nanoplates have better electrochemical performance with high specific capacity, long cycle life, and good rate capability, indicating that they are promising candidates for LIB anodes.
