**Abstract**—In recent year, auction is used to solve the problem that the requirement and supply of license plate is not equal. The common rule of auction is that the bidders win the license plate by price order after submitting the price at the same time. The discriminate auction model of license plate is built in this article to find the best bid strategy. Then classify the bidders by different risk appetite. The winning probability of different risk appetite is analyzed. The best valuation expression can be got according the different probability.

**Key words:** License plate auction, different risk appetite

I. THE DISCRIMINATE AUCTION MODEL

Model hypothesis:
(1) The number of the same License plate is \(k\)
(2) The number of the bidders is \(n\) \((n \geq k)\)
(3) Each auctioneer can only get a license plate
(4) The auction is a non-cooperative game
(5) The valuation of bidders obey the same distribution function and won’t change according to other information.

Every bidder have the valuation \(v_i\) of the auction, the valuation of bidders is independent and obey the same distribution function \(F(v_i)\). \(F(v_i)\) is strictly increasing and differentiable in the Domain \([0, \theta]\). And the probability density function if \(f(v_i)\). Every bidder will submit the price \(g_i\) according to the valuation \(v_i\), \(g_i = g(v_i)\) is monotonically increasing and differentiable. According to the auction \(g_i \leq v_i\).

Let’s investigate the bidder \(X\). His valuation is \(v_x\). His bid function is \(G = g_x = g(v_x)\). Other bidders’ valuation and bid function is \(v_i, g_i = g(v_i)\) \((i = 1, 2 \ldots n \text{ and } i \neq x)\).

\(P_x(\text{win})\) Represents the probability that the bidder \(X\) win. We definite the income function of the bidder \(X\)

\[R_x = (v_x - G) \times P_x(\text{win})\]

We introduce the inverse function \(h(g_i), h(g_i) = v_i\). The function \(h\) is monotonous, so

\[P_x(\text{win}) = P(G > \{g_i\}_1) + P(G > \{g_i\}_2) + \ldots + P(G > \{g_i\}_{k-1}) = C^{n-1}_{k-1}F[h(G)]^{n-1}[1-F(h(G))] + \ldots + C^{n-1}_{k-1}F[h(G)]^{k-1}[1-F(h(x))]^{k-1}\]

So,

\[R_x = (v_x - G) \times \sum_{i=1}^{k} C^{n-1}_{k-1}[1-F(h(G))]^{k-i}F(h(G))^{k-i}\]

To solve the problem conveniently. We introduce the expression \(L_i(x) = [1 - F(x)]^{-1}F(x)^{x-i}\), so

\[R_x = (v_x - G) \times \sum_{i=1}^{k} C^{n-1}_{k-1}L_i[h(G)]\]

For the bidder \(X\), His best bid \(G\) is the bid that can make the biggest \(R_x\). So

\[\frac{\partial R_x}{\partial G} = (v_x - G) \times \sum_{i=1}^{k} C^{n-1}_{k-1}L_i[h(G)] \times h'(G) - \sum_{i=1}^{k} C^{n-1}_{k-1}L_i[h(G)] = 0\]

For the bidder \(X\):
\[G = g_x = g(v_x) = v_x, h'(G) = 1 / g'(v_x)\], then integral

\[G = v_x - \frac{\sum_{i=1}^{k} C^{n-1}_{k-1} \int_0^x L_i(y)dy}{\sum_{i=1}^{k} C^{n-1}_{k-1}L_i(v_x)}\]
Let put \( L_i(x) = \left[ 1 - F(x) \right]^{i-1} F(x)^{n-i} \) into the expression. We get the best bid strategy.

II. BIDDER’S BEST STRATEGY WITH DIFFERENT RISK APPETITE

In reality, everybody’s risk appetite is different. For the bidders has different risk appetite, their bids are reason reasonably different. We classify the bidders has different risk appetite for three categories. The three categories are risk bidders, neutral bidders and conservative bidders. Their corresponding bidding function is \( g_1, g_2, g_3 \). The number of three kinds of bidders are \( n_1, n_2, n_3 \) \((n_1 + n_2 + n_3 = n)\). The number of three kinds of bidders winning are \( k_1, k_2, k_3 \), The remaining assumptions are the same as the above model.

Considering the bidder \( X \), His valuation and bid is \( v_x \) and \( G \). We definite the income function

\[
R_x = (v_x - G) \times P_x(\text{win})
\]

Bidder \( X \) is the bidders of three categories. We definite the three bids \( G_1, G_2, G_3 \) according to three categories. So the income function is

\[
R_x = (v_x - G_1) \cdot P_x^{\text{risky}}(\text{win}) + (v_x - G_2) \cdot P_x^{\text{neutral}}(\text{win}) + (v_x - G_3) \cdot P_x^{\text{conservative}}(\text{win})
\]

We introduce the symbol \( \{g_i\}_k \). The symbol \( \{g_i\}_k \) represents the \( k \)th bid after arranging descending bid \( g_i \). As shown on the right, \( \{g_i\}_k \) intersects function \( g_1, g_2, g_3 \), and the abscissa of intersection point are \( v_1, v_2, v_3 \). (It mean the lowest valuation of the three kinds of bidders if they win). You can see this situation in the Figure 1.

Considering the risk bidder: the number of the bidders are \( n_1 \). \( v_1 \) is the lowest valuation if they win \( F(v_1) \) represent the probability that valuation is less than \( v_1 \). So the number of the risk bid winning is \( k_1 = [1 - F(v_1)] \cdot n_1 \).

\[
P_x^{\text{risky}}(\text{win}) = \sum_{i=1}^{k_1} C_{n_1-1}[1 - F(v_i)]^{i-1} F[v_i]^{n_1-i}, \quad \text{and} \quad k_1 = [1 - F(v_1)] \cdot n_1
\]

As the same inference, we can get the winning probability of the neutral bidders and conservative bidders.

So

\[
R_x = \left[ v_x - g_1(v_x) \right] \sum_{i=1}^{k_1} C_{n_1-1}[1 - F(v_i)]^{i-1} F[v_i]^{n_1-i} \cdot \frac{n_1}{n} + \\
\left[ v_x - g_2(v_x) \right] \sum_{i=1}^{k_2} C_{n_2-1}[1 - F(v_i)]^{i-1} F[v_i]^{n_2-i} \cdot \frac{n_2}{n} + \\
\left[ v_x - g_3(v_x) \right] \sum_{i=1}^{k_3} C_{n_3-1}[1 - F(v_i)]^{i-1} F[v_i]^{n_3-i} \cdot \frac{n_3}{n}
\]

\[
k_1 = [1 - F(v_1)] \cdot n_1 \quad k_2 = [1 - F(v_2)] \cdot n_2 \quad k_3 = [1 - F(v_3)] \cdot n_3
\]

Because the bidding strategy is different according to the different risk appetite, we want to find the best valuation. The best valuation \( v_x \) is what make the \( R_x \) biggest.
